Accepted: 15 September 2006 doi:10.1111/j.1463-6409.2006.00266.x Kergoat, G. J., Silvain, J.-F., Buranapanichpan, S. & Tuda, M. (2007). When insects help to resolve plant phylogeny: evidence for a paraphyletic genus *Acacia* from the systematics and host-plant range of their seed-predators. — *Zoologica Scripta*, *36*, 143–152.

In this study we use an indirect method to address the issue of the systematics of the large and economically important genus Acacia (Leguminosae, Mimosoideae, Acacieae). We propose the use of host-preference data in closely related insect species as a potentially useful tool to investigate host systematic issues, especially when other approaches yield inconsistent results. We have examined the evolution of host-plant use of a highly specialized group of seed-feeders who predate Acacia - the seed-beetles (Coleoptera, Chrysomelidae, Bruchinae). First, the evolution of host-plant preferences in a large clade of Bruchidius species was investigated using molecular phylogenetics and character optimization methods. Second, the scope of our study was enlarged by critically reviewing the host-plant records of all bruchine genera associated with Acacia. Both morphological and molecular data were used to define relevant insect clades, for which comparisons of host-plant range were performed. Interestingly, the analyses of hostplant preferences from 163 seed-beetle species recovered similar patterns of host-plant associations in the distinct clades which develop within *Acacia* seeds. Our results clearly support the hypothesis of Acacia being a paraphyletic genus and provide useful insights with reference to the systematics of the whole subfamily as well. This study should also be of interest to those involved in the numerous biological control programs which either already use or aim to use seed-beetles as auxiliary species to limit the propagation of several invasive legume tree species. Introduction

Within the economically important family Leguminosae, members of the large genus *Acacia* (Mimosoideae, Acacieae) have for many years provided the subject-matter of numerous studies with regard to their ecological and economic importance. Since its description in 1754 by P. Miller, the nomenclatural history of *Acacia* has been a complex one, with numerous controversial works and proposals (reviewed in Maslin *et al.* 2003). Recently, the Nomenclature Section of the 17th International Botanical Congress (ICB) ratified the retypification of the genus, following the proposal of Orchard & Maslin (2003) to change the type of *Acacia* from *A. scorpioides* (syn. *A. nilotica*) to *A. pennivernis* (see Maslin 2005 and Seigler *et al.* 2006 for a review of the nomenclatural implications).

Most *Acacia* species are characterized by free filaments of the stamens (Bentham 1842, 1875; but see Vassal 1981); however, as stressed by Miller & Bayer (2003), their positioning as a natural group is not supported by any synapomorphic characters. While the subdivision of the genus into smaller genera has been repeatedly proposed by many authors in the past (see in particular the contribution of Pedley 1986), it is only recently that new insights have been obtained following the plethora of phylogenetic studies using molecular markers (e.g. Clarke *et al.* 2000; Robinson & Harris 2000; Luckow *et al.* 2003; Miller & Bayer 2003; Miller *et al.* 2003). Table 1 Main Acacia classification systems.

*Formerly genus 'X' in Maslin et al. (2003).

As emphasized by Maslin et al. (2003), these studies indicate that the genus is paraphyletic and also stress the need of dividing the 1350 Acacia species into at least five distinct genera. In this paper we have followed the classification proposed by Maslin et al. (2003), in which Acacia sensu lato is treated as comprising multiple genera (see Table 1). Although the paraphyletic status of the genus is now widely acknowledged, numerous questions remain unanswered due to the inconsistency of the tree topologies obtained in various studies. For instance, the issue of the respective phylogenetic positions of the various Acacia s.l. lineages within subfamily Mimosoideae is still debated, with several molecular studies (Luckow et al. 2003; Miller & Bayer 2003; Miller et al. 2003) suggesting that the genus Vachellia (syn. Acacia subgen. Acacia in Vassal's classification) is more closely related to plants belonging to the tribe Mimoseae, while the four other Acacia genera are clustered with members of the Ingeae tribe. In this context it seems appropriate to provide additional insights into Acacia s.l. systematics by using other sources of information.

Phytophagous insect species are mostly oligophagous or monophagous and usually feed on a restricted number of host-plant taxa (Strong et al. 1984; Futuyma & Moreno 1988; Jaenike 1990; Ward & Spalding 1993; Bernays & Chapman 1994; Funk et al. 2002; but see also Novotny et al. 2002). Most of them also specialize in specific host-plant tissues like stems or leaves (Bernays & Chapman 1994). The latter trend, towards trophic specialization, is even more marked in insect groups which feed on internal tissues (e.g. roots, seeds or stems; Gaston et al. 1992; Anderson 1995; Marvaldi et al. 2002). Interestingly, numerous studies (e.g. Mitter et al. 1991; Farrell 1998) have revealed that these restricted feeding habits are often conserved over long time periods, resulting in a evolutionary pattern which is commonly referred as 'taxonomic conservatism in host-plant use'. In the latter pattern, closely related insects generally feed on closely related hostplants. In some past studies (Eastop 1979; Johnson 1980), the analysis of the host-plant preferences of groups of specialized phytophagous insects has been proposed as a relevant means of investigating the systematics of their host-plants. The argument is that these predators are host-specific, enabling us to trace the evolutionary trajectories of their hosts fairly closely. Here we propose investigating the systematics of the genus *Acacia* by using evidence from the systematics and host-plant range of some of its seed-predators.

Numerous guilds of seed-predators develop within the seeds of most *Acacia s.l.* species. The specialized seed-beetles (Coleoptera, Chrysomelidae, Bruchinae) are especially noteworthy, because members of seven bruchine genera (*Acanthoscelides, Bruchidius, Caryedon, Merobruchus, Mimosestes, Pseudopachymerina* and *Stator*) are known to develop in *Acacia s.l.* seeds (Borowiec 1987). Previous studies have also demonstrated that bruchines generally exhibit a strong level of taxonomic conservatism in host-plant use (Silvain & Delobel 1998; Kergoat *et al.* 2004, 2005a, 2005b; Tuda *et al.* 2006).

In this paper we hypothesize that the study of host-plant associations in these bruchines may provide meaningful insights into Acacia s.l. systematics. We test this hypothesies by first investigating in depth the phylogenetic relationships of a large Palaeotropical clade of Bruchidius species associated with an exceptionally diverse set of Mimosoideae species belonging in particular to the tribe Ingeae and to the genera Senegalia and Vachellia, whose phylogenetic positions among Mimosoideae are unresolved. We use the resulting molecular phylogeny to discuss the evolution of host-plant preferences in this group by employing maximum likelihood optimization methods. Second, we enlarge the scope of our study by critically reviewing the host-plant records for all the bruchine genera which are known to develop within Acacia s.l. seeds. For six genera, we have defined relevant insect clades whose host-plant ranges were analysed. Finally, in the seed-feeding groups studied, we discuss the observed patterns of hostplant association with reference to extant phylogenetic

hypotheses for the subfamily Mimosoideae in order to help clarify the puzzling issues of *Acacia s.l.* systematics.

Materials and methods

Phylogenetic analyses – Evolution of bost-plant association

Thirty *Bruchidius* species belonging to a monophyletic group (Kergoat & Silvain 2004; Kergoat *et al.* 2005b), herein referred to as 'clade I' and three outgroups (i.e. *Bruchidius chloroticus, Gibbobruchus* sp. and *Pachymerus cardo*) were sampled (see Table 2). In comparison with a previous study (Kergoat *et al.* 2005b), our sampling is much more representative of the diversity of this Palaeotropical group, as it encompasses Asian species. The use of more extensive sampling is note-worthy because it provides firmer ground on which to discuss the evolution of the whole group.

Sequences were obtained for four genes: mitochondrial 12 s rRNA (12S), cytochrome *b* (Cyt b) cytochrome *c* oxidase subunit I (COI), and nuclear 28s rDNA (28S) (see Kergoat

et al. 2004, 2005b for a list of primers and PCR cycling conditions). Since the sequences of ribosomal genes (i.e. 12S and 28S) presented some variations in length, their alignment was performed using ClustalX (Thompson *et al.* 1997) with default option settings. Manual correction of small misalignments was conducted in Seaview (Galtier *et al.* 1996). The resulting combined data set (2944 bp in length) was deposited in TreeBase under accession number SN2846.

As a first approach to reconstructing the molecular phylogenies of the sampled *Bruchidius* species, we carried out unweighted maximum parsimony (MP) analyses using PAUP* ver. 4.0b10 (Swofford 2003). Under MP, we performed heuristic searches by using tree-bisection-reconnection (TBR) branch swapping, 1000 random-addition replicates, and a MaxTrees value of 1000. To test the congruence of the phylogenetic information carried out by the four genes, the incongruence length difference test (ILD; Farris *et al.* 1994) was used, with all invariant characters excluded (Cunningham 1997). Since the result of the ILD test was not significant (P > 0.05), we chose to perform an analysis of the combined data set. Relative support of nodes for MP analyses was assessed by nonparametric bootstrap (Felsenstein 1985) procedures, with 1000 pseudoreplicates of 1000 random-addition replicates used. Nodes supported by bootstrap values $\geq 70\%$ were considered to be strongly supported (Hillis & Bull 1993).

We then conducted Bayesian inference (BI) analyses using MrBayes ver. 3.1.1 (Huelsenbeck & Ronquist 2001). We carried out partitioned analyses of the combined data set to increase the fit of the evolutionary models with the data (Yang 1996; Nylander et al. 2004; Brandley et al. 2005). For each gene (one partition per gene was used), the best-fit model of evolution was determined by using the Akaike information criterion (AIC) as implemented in Modeltest ver. 3.06 (Posada & Crandall 1998). Two independent BI runs were conducted to identify whether convergence of clade posterior probabilities (CPP) had been reached (Huelsenbeck et al. 2002). For each run, four incrementally heated Markov chains of 2×10^6 generations were used, with random starting trees, default priors and trees sampled every 100 generations (branch lengths were also saved). A burn-in period of 1×10^5 generations was defined for all BI runs and stationarity was assessed graphically. Support of nodes for BI analyses was provided by CPP estimates. Only clades with posterior probabilities $\geq 90\%$ were considered as well supported in BI analyses, in agreement with recent studies which have suggested that CPPs are less conservative than nonparametric bootstrap values (Alfaro et al. 2003; Erixon et al. 2003).

The evolution of host-plant association in *Bruchidius* species belonging to clade I was investigated by using maximum likelihood (ML) reconstructions. These were preferred over MP reconstructions because they allow the assessment of uncertainty in ancestral trait reconstruction and because they can take into account branch length information (Schluter *et al.* 1997; Pagel 1999). We used Multistate ver. 0.8 (Pagel 2003) to carry out local optimizations; a simpler model (in which forward and backward rates were constrained to be equal) was used to avoid over-parameterization issues (Pagel 1999). We considered that the support of one state over another (at a given node) was significant if the difference between their log-likelihoods was greater than or equal to 2.0 (Schluter *et al.* 1997; Pagel 1999).

In an initial attempt to categorize host-plant information, we used the following character states: (i) tribe Ingeae; (ii) genus *Senegalia* (syn. *Acacia* subg. *Aculeiferum*); (iii) genus *Acacia* (syn. *Acacia* subg. *Phyllodineae*); (iv) genus *Vachellia* (syn. *Acacia* subg. *Acacia*); (v) tribe Mimoseae; (vi) subfamily Caesalpinioideae; (vii) other legumes. However, it appeared that some species in our data-set were able to develop on plants from the tribe Ingeae and on plants belonging to either the genus *Senegalia* or the genus *Acacia*. To deal with these multiple associations in our optimizations, we chose to consider only the most-represented host-plant tribe or genera in the coding of the corresponding character states. Consequently, one of the seven character states (i.e. genus *Acacia*) was discarded in our analyses, and only six were retained to study the evolution of host-plant association in this clade. While being not entirely satisfactory, this treatment of data was preferable to alternative methods which generally produce their own bias (Lopez-Vaamonde *et al.* 2003). In addition, phylogenetic structure in host-plant associations was assessed using the permutation tail probability test (PTP; Faith & Cranston 1991), as implemented in PAUP*. Within-character randomization was only applied to the ingroup taxa (i.e. *Bruchidius* clade I species) to avoid misleading PTP scores (Trueman 1996).

Host-plant records

Host-plant data were carefully reviewed and doubtful records discarded from the analysis (following Kergoat et al. 2005a). All the names from the literature were also checked by using the International Legume Database and Information Services database (ILDIS; http://www.ildis.org), and updated when necessary. Data based on the rearing of adults from seeds collected in the field were also preferred. Thanks to the rigorous fieldwork of several reputable entomologists such as L.J. Bottimer, C.D. Johnson and J.M. Kingsolver, reliable host-plant records were available for all studied New World genera (Acanthoscelides, Merobruchus, Mimosestes, Pseudopachymerina and Stator). This was also the case for the Old World genus Bruchidius, for which considerable sampling in the field has recently been performed in Africa (see Kergoat et al. 2005b) and Asia (this study). In addition, reliable hostplant records for this genus were found in the literature (e.g. see Arora 1977, 1980; Gillon et al. 1992). By contrast, and as stressed by the recent review of Johnson et al. (2004), reliable host-plant records were missing for the genus Caryedon. Although some trends toward taxonomic conservatism in host-plant use are discernible in this genus (e.g. all members of the species-group interstinctus appear to feed exclusively on Vachellia species), we have decided not to take this genus into account in our study.

For each bruchine study group, preference for a given subset of host-plants was assessed by using Fisher's exact test. Expected proportions (based on the host-plant records from all studied species) were compared with the observed proportions in each study group to test whether any difference of proportions was significant (see Table 3).

Definition of study groups

While considerable morphological and molecular evidence supports the monophyletic status of genera *Merobruchus*, *Mimosestes*, *Pseudopachymerina* and *Stator* (Borowiec 1987;

Silvain & Delobel 1998; Johnson et al. 2004; Morse & Farrell 2005; Katoh, pers. comm.), it appears that two genera (Acanthoscelides and Bruchidius) are likely paraphyletic (Borowiec 1987; Kergoat & Silvain 2004; Kergoat et al. 2005a; Alvarez et al. 2006). For these two large genera (which both comprise over 250 species) we have chosen to take into account only those clades associated with Mimosoideae. Within Bruchidius all mimosoid feeders belong to two well-defined clades (here referred to as clades I and II; see also the pruned tree in Fig. 1), whose monophyletic status is strongly supported by both molecular (Kergoat & Silvain 2004; Kergoat et al. 2005b) and morphological evidence (Anton & Delobel 2003; Kergoat & Silvain 2004). With regard to Acanthoscelides, almost all mimosoid feeders are found in five morphologically well-supported taxonomic groups (Johnson 1983, 1990). Although no comprehensive molecular studies have hitherto been made on a large sampling of these species, recent molecular phylogenetic reconstructions have nonetheless suggested that mimosoid feeder species constitute a monophyletic group (Kergoat *et al.* 2005a; Alvarez *et al.* 2006).

Results and discussion

Phylogenetic analyses – evolution of bost-plant association

For *Bruchidius* clade I, we present the phylogenetic hypothesis resulting from the BI analyses (Fig. 1). Overall, this topology is well-supported, with a mean CPP value of 84.2%. The BI tree is largely compatible with the two equiparsimonious trees (length of 3609 steps) recovered under MP, and the topology differences observed among the two approaches (i.e. BI and MP) have no impact on the following discussion.

Evolutionary conservatism in host-plant associations among clade I species is suggested by the result of the PTP test (P < 0.0001) which indicates a significant (nonrandom) phylogenetic structure. This result is also supported by the ML reconstructions of ancestral character states which reveal a statistically supported trend toward taxonomic conservatism in two clades associated, respectively, with members of tribe Ingeae and of genus *Vachellia* (see Fig. 1). With the exception of two terminal nodes, the ML optimizations do not recover other statistically supported ancestral character states.

However, a close examination of the probabilities associated with each ancestral character state for all nodes (data not illustrated) indicate that two of them (tribe Ingeae and genus Senegalia) account for the majority of the observed proportions. Along with the fact that some species are able to feed on Ingeae and on members of Senegalia, this finding suggests a quite dynamic evolutionary pattern in which host-shifts between Ingeae and Senegalia are also facilitated because the two groups share the same main toxic compound (i.e. the nonprotein amino acid albizziine; see Kergoat et al. 2005b). By contrast, Vachellia spp. are well characterized by the sequestration in their seeds of the nonprotein amino acid Nacetyldjenkolic acid (Seigler 2003; Or & Ward 2004). All of these elements provide grounds for supporting the hypothesis of a close relationship between the two groups as well, suggesting that Senegalia is less closely related to Vachellia than to Ingeae.

Host-plant range of the mimosoid feeder bruchines

Host-plant records from 163 species were analysed (see supplementary material for a complete list of host-plant records). It is interesting to note that records of species feeding on the species-rich genus *Acacia* (for which nearly 1000 species are known) were exceptionally scarce (only 4 of the 163 studied species are associated with *Acacia*). The most likely explanation of this surprising observation can be found in the very poor knowledge of the Australian bruchine fauna (Borowiec 1987), as most of the known *Acacia* species occur in Australia. At the species level, the studied bruchines exhibit a strong trend toward specialization: nearly half of the species

Fig. 1 Molecular systematics and optimization of host-plant use in *Bruchidius* clade I species. On the left, the pruned tree indicates the respective positions of both *Bruchidius* clade I and clade II species in the study of Kergoat & Silvain (2004). On the right, the phylogenetic relationships of clade I species are presented using the topology obtained under BI, with numbers at nodes indicating CPP values. Optimization of host-plant use was performed under Multistate using both the topology and branch lengths of BI analyses. Significantly supported character states at nodes are indicated by the various coloured circles (see the figure caption for details on host-plant groups) while their absence is indicated by uncoloured (grey) circles . The probabilities of the majority character states of two nodes are also listed in red. For illustrative purposes, a photograph of a *Bruchidius dichrostachydis* specimen is also provided.

(47.23%) are strictly monophagous, while the vast majority are oligophagous, mostly feeding on plants either from the same genus (82.82%) or tribe (88.34%).

The host-plant ranges of each group of mimosoid feeder are schematized in Fig. 2 (with the exception of the monospecific genus *Pseudopachymerina*, which only feeds on three species of *Vachellia*). As indicated in the figure caption, multiple users of the same host-plant species by several members of a given group is indicated by the various proportions illustrated in the pie charts.

Several observations can be made from analysis of the hostrange of the studied seed-beetles. First, a statistically significant bias in host-plant preferences was recovered in six of the seven studied groups of mimosoid feeder bruchines (P < 0.05, Fisher's exact test; see Fig. 2 for details); thus suggesting a far from random pattern of host-use in the mimosoid feeder groups. In *Acanthoscelides, Bruchidius* clade II and *Mimosestes* species, a similar pattern is recovered, as they are preferentially associated with one of the five recently accepted *Acacia* genera (namely *Vachellia*). In addition, they are found on Caesalpinioideae (members of tribes Cassieae and Caesalpinieae only) and on Mimosoideae (members of tribes Mimoseae and Parkieae).

By contrast, species of Merobruchus feed on a completely different set of host-plants, as they develop on the four other Acacia genera (Acacia, Acaciella, Mariosousa and Senegalia) and on members of the tribe Ingeae (Mimosoideae). Finally, in Bruchidius clade I and genus Stator, species of seed-beetles are able to feed on a larger set of host-plants which includes both Vachellia and other Acacia s.l. genera. For these two clades, molecular phylogenies permit discussion in greater depth of the evolution of host-plant range. With regard to Stator, the study by Morse & Farrell (2005) has revealed complex patterns of host-plant associations that are not only influenced by the relatedness of host-plants, but also by the oviposition behaviours of the females. Interestingly, their study indicates that the species that are only associated with Vachellia are closely related, thus suggesting that host-shifts to Vachellia are quite conservative. For both Stator (with the exception of the most polyphagous species such as Stator pruininus) and Bruchidius clade I species it thus appears that feeding on Vachellia and feeding on other Acacia s.l. genera (plus Ingeae) are generally mutually exclusive.

The above information is especially useful when considering (see Fig. 2) the various competitive phylogenetic hypotheses from five recent molecular studies on Mimosoideae (Clarke *et al.* 2000; Robinson & Harris 2000; Miller & Bayer 2003; Miller *et al.* 2003; Luckow *et al.* 2003). Two main patterns are recovered in the studied mimosoid feeder groups. In the first, the vast majority of species feed on *Vachellia* but also on members of tribes Cassieae, Caesalpinioideae, Mimoseae and Parkieae. In the second, the vast majority of species feed on other *Acacia*

s.l. genera but also on members of the tribe Ingeae. Interestingly, the two patterns of host-plant associations are mutually exclusive, with only a few exceptions to the rule (e.g. some polyphagous *Stator* species or the two *Bruchidius* species associated with Caesalpinioideae).

Comparison of the above patterns with the existing plant phylogenies suggests a strong correspondence between the host-plant phylogenies and the host-range of the mimosoid feeders, as some groups of beetles are either associated with basal species of Mimosoideae (i.e. *Vachellia* and members of tribes Mimoseae, Parkieae) and Caesalpinioideae (tribes Cassieae and Caesalpinieae only) or with more derived species of Mimosoideae (i.e. genera *Acacia, Acaciella, Mariosousa, Senegalia* and members of the tribe Ingeae). The host-plant ranges of the seed-beetles do not overlap, thus suggesting that *Vachellia* spp. are not related to other species of *Acacia s.l.*, in agreement with the hypothesis of a paraphyletic genus *Acacia s.l.*

In summary, our results are consistent with those of the phylogenetic studies which suggest that Vachellia species are more closely related to basal mimosoid tribes, while other Acacia s.l. species are more closely related to the derived tribe Ingeae. They also suggest that basal mimosoids are more closely related to the tribes Cassieae and Caesalpinieae of the Caesalpinioideae, in agreement with previous studies on legume systematics (Käss & Wink 1996; Doyle et al. 1997; Bruneau et al. 2001). Since numerous species of seed-beetles are actually used in various biological control programs (e.g. see Fowler et al. 2000; Radford et al. 2001; van Klinken 2004), we stress the importance of carefully assessing the risks of possible host-shifts toward nontarget native plants, especially when dealing with invasive Acacia s.l. species. For instance, plants of the tribe Ingeae should be included in host-range tests of any biological control programs directed against Senegalia species. Since the pattern of host-plant association is quite conservative in bruchines, we also suggest studying the host-ranges of the related species of any seedbeetle species to be used in a biological control program.

Acknowledgements

We thank A. Delobel for invaluable taxonomic assistance and comments on the manuscript, G. Couturier, H. Delobel, B. Le Rü, C. Niyomdham and Y. Tateishi for providing interesting specimens, K. Morimoto for additional information on host-preferences of Japanese bruchine species, P. Tewari for information on Indian bruchines and for providing access to the publications of Arora. GJK also thanks M.-L. Cariou and M. Takagi for laboratory support in France and Japan, respectively. We thank P. Ericson and one anonymous reviewer for comments that helped improve the paper. This research was partially supported by a postdoctoral grant (grant number: PE05017) from the Japanese Society for the Promotion of Science (JSPS) for GJK.

Fig. 2 Host-plant systematics and known host-plant range of the seed-beetle genera associated with *Acacia* species. On the left, various phylogenetic hypotheses from five recent molecular studies on Mimosoideae are illustrated using pruned trees. On the right, the known host-plant range of each genus (or subset of a given genus in the case of *Acanthoscelides* and *Bruchidius* spp.) is summarized using a pie chart. Multiple uses of the same host-plant species by several members of a given genus (or a subset of a genus) were summed up to draw the various proportions which are depicted in the pie diagrams. For each host-plant category (e.g. tribe Ingeae or genus *Vachellia*) the known number of plant species (and also the number of genera when considering a suprageneric category) predated by a given insect group is also provided. Asterisks indicate statistically supported preferences for given subsets of host plant (using Fisher's exact test). Finally, the number of species analysed for each insect group is given in parentheses.
